Final Report for Developing Equalization Techniques for use with Bandwidth Efficient Modulation Methods

Subtitle: Data Compression Techniques to Reduce Bandwidth

### **Abstract**

Bandwidth is a precious commodity. In order to make the best use of what is available, better modulation schemes need to be developed, or less data needs to be sent. This paper will investigate the option of sending less data via data compression. The structure and the entropy of the data determine how much lossless compression can be obtained for a given set of data. This paper shows the data structure and entropy for several actual telemetry data sets and the resulting lossless compression obtainable using data compression techniques.

# Final Report for Developing Equalization Techniques for use with Bandwidth Efficient Modulation Methods

Subtitle: Data Compression Techniques to Reduce Bandwidth

### **Project Summary:**

### **Objectives:**

- 1. Analyze the performance of the 32 QAM in multipath channels.
- 2. Develop adaptive filtering equalization for 32 QAM in multipath channels.
- 3. Analyze the performance of pulse shaped 8 PSK in multipath channels.
- 4. Develop adaptive filtering equalization for 8 PSK in multipath channels.
- 5. Investigate the use of interleaving for the 32 QAM and 8 PSK modulation techniques in a multipath environment.
- 6. Develop reports detailing work and recommendations.
- 7. Perform statistical analysis on the telemetry data to determine possible amounts of compression.
- 8. Apply arithmetic, Ziv-Lempel, Huffman, and Rice data compression techniques to the data.
- 9. Test data compression techniques in a channel simulation to test the robustness of the code.
- 10. Adapt the Rice algorithm to better handle telemetry data.
- 11. Complete Final report.

### Accomplishments:

Objectives 1 through 6 have not been met and were changed. To test the 32 QAM and 8 PSK in the multipath channels required the appropriate channel model be available. Brigham Young University (BYU) was developing this model when this project started, and the model was not available. During the progress of this project, the objectives changed. Discussion with ARTM led to a different area of concentration. Work by others was proving successful with FQPSK, so this work on modulation was changed to an emphasis on data compression. Reducing the amount of data to be sent can reduce the bandwidth and thus accomplish the same results as the 8 PSK, and 32 QAM.

Objectives 7 through 9 were completed. Data compression results indicate that data compression is viable, channel simulations do indeed indicate that data compression alone would be unfeasible, but adding channel coding to protect the data again makes this data compression with channel coding a viable option.

Objective 10 is still in process. The work was not completed due to the extensive amount of time it would take to complete the task, and student employment problems. Current results do indicate that an adaptation of the Rice algorithm would work well for telemetry data.

### Personnel Support:

1. One Faculty member (the PI)

2. One technician (for help in setting up the computers in the lab)

3. Five undergraduate students (total at various times, no student worked more than part-time. Two students worked for 1 year, and 2 other students worked for 6 months. The last student was supported by an on campus research grant for 2.5 months) The students were:

Jonathan McMillan – worked on learning simulations and getting simulink to work; attended 1998 ITC conference.

James Woods – wrote programs for statistical analysis, attended 1998 ITC conference.

Shakti Davis – worked on the error analysis, and channel simulations, attended 1999 ITC conference

Kendall Mauldin – began looking into the Rice algorithm and made recommendations to modify it, attended 1999 ITC conference.

Enrique Sanchez – started modifications of Rice algorithm but was unable to complete the work.

### Publications:

Paper at the International Telemetering Conference: "Data Compression Statistics and Implications", ITC October 1999

### Interactions/Transitions:

1. Participated in Advanced Range Telemetry (ARTM) group meeting in the spring (1998).

2. Consultative/advisory functions: Communicate with BYU regarding our related projects

3. Participated in Advanced Range Telemetry (ARTM) group meeting at the ITC (1998, 1999)

4. Participated in Advanced Range Telemetry (ARTM) communications via email and phone. New error sets were to be sent in January (1999) – none received as of this date.

New Discoveries, inventions, or patent disclosures: None

Honors/Awards: None

### Introduction

Bandwidth is a precious commodity. It has become imperative that bandwidth is used efficiently. To this end, data needs to be reduced, or modulation techniques need to be used t minimize the bandwidth. Data compression (coding) is one technique to reduce the bandwidth needed to transmit data. The bit rate = R = (# of data bits sent)/ sec. The bandwidths for BPSK are (6):

3-db bandwidth 0.88 R null to null bandwidth 1.0 R

As can be seen if R decreases, the so to does the bandwidth. The goals of data coding are to:

- Reduce the amount of data
- Find codes that take into account redundancy, structure, and patterns
- Break up data into random groups

Entropy is a measure of the information content of the data, a measure of the uncertainty or randomness of the data, and can be used to indicate how many bits would be needed to encode the data if the data are independent.

If X is a random variable, process, or data to be coded (usually X is discrete, but doesn't have to be); which takes on the values  $X_1, X_2, ..., X_n$ ; and  $p_i$  is the probability that  $X_i$  occurs, then the entropy

$$H(X) = -\sum_{\text{all } i} p_i \log(p_i)$$

If the log is base two, then the units will be bits and will indicate the number of bits needed to code the message without loss of information. In order to calculate this quantity, the all of the marginal and joint probabilities have to be known. This is not usually possible. Most of the time, the entropy is estimated by the first order probabilities (that is the probabilities of the individual symbols). A second order probability is based on grouping two symbols at a time; third order is three symbols at a time. etc. The true entropy is based on the nth order probabilities as n approaches the size of the data file to be transmitted.

Independence of data means that the probability of  $(X_1X_2)$  is the product of the individual probabilities.

### Example:

Suppose that the original data is given by: 0 1 2 2 2 3 4 4 4 5 6 6 7 8 8 8

To code this directly in binary would take 4 bits per symbol. The amount of data compression can be found by using entropy and assuming independence of the data. To find the first order entropy, the probability of each symbol would need to be found.

Symbol	Freq.	$p_i = freq/(total \#$	-p <sub>i</sub> log p <sub>i</sub>
	•	symbols)	
0	1	0.0625	0.25
1	1	0.0625	0.25
2	3	0.1875	0.453
3	1	0.0625	0.25
4	3	0.1875	0.453
5 .	1	0.0625	0.25
6	2	0.125	0.375
7	1	0.0625	0.25
8	3	0.1875	0.453
overall	16	1.0	Data entropy=2.983

This gives a reduction of about 25%. The % compression can be found by

compression ratio = 
$$1 - \frac{\text{compressed file size (average coded symbol size)}}{\text{orignal file size (uncoded symbol size)}}$$

If the data are independent and if the above is an accurate representation of the entropy, then the best compression that would be possible is 2.983 bits/symbol. The following table shows the results obtained if the data are grouped by two symbols at a time:

Two bits New symbol		Freq	Prob	-P <sub>i</sub> log P <sub>i</sub>	
01	0	1	0.125	0.375	
22	1	1	0.125	0.375	
23	2	1	0.125	0.375	
44	3	1	0.125	0.375	
45	4	1	0.125	0.375	
66	5	1	0.125	0.375	
78	6	1	0.125	0.375	
88	7	1	0.125	0.375	
totals		8	1.0	3.0	

This gives an entropy of 3.0 (still a decrease from the original, but an apparent increase from the first order entropy). This really isn't an increase. This entropy is for two symbols at a time and the compression ratio will be 1-(3x8)/(4x16) = 63%.

These entropies were calculated assuming independence of the data. Suppose there is a relationship between the data. One way to examine this is to look at the differences between neighboring data. To start, leave the first data symbol alone, and then subtract the second from the first, then the third from the second, etc. This gives:

Original data: 0 1 2 2 2 3 4 4 4 5 6 6 7 8 8 8 Differenced: 0 1 1 0 0 1 1 0 0 1 1 0 1 0 0

In this case, there are two possible symbols (0 and 1), each occurring 8 times. This will give a probability of ½ for each symbol, and an entropy of 1. We could now code the original data with 16 bits of data where the original would take 4 times that many bits. This would give a compression ratio of 75% over the original data. Since we get compression by differencing the data, this indicates that there is correlation between the data and that they are not independent. Suppose now that the differenced data are grouped two at a time as follows:

### 01 10 01 10 01 10 11 00

### Analysis of this data gives

Two bits	New symbol	Freq	Prob	-P <sub>i</sub> log P <sub>i</sub>
01	0	3	0.375	0.531
10	1	3	0.375	0.531
11	2	1	0.125	0.375
00	3	1	0.125	0.375
totals		8	1.0	1.811

The compression ratio for this grouping is: 1-(8x1.811)/(4x16) = 77%Notice how the compression ratio continues to increase, meaning that the file size gets smaller. Continuing to group one more time – grouping by fours gives:

### 0110 0110 0110 1100

This has just two symbols. 0110 occurs three times, and 1100 occurs only once. This will give:

Two bits	New symbol	Freq	Prob	-P <sub>i</sub> log P <sub>i</sub>
0110	0	3	0.75	0.311
1100	1	1	0.25	0.5
totals		4	1.0	0.811

In this case, with just two symbols to code, the compression ratio becomes:

1- 
$$(4x0.811)/(4x16) = 95\%$$

The above is just an example to demonstrate how compression can occur. The compression ratio is just a prediction of the actual compression. In order to achieve this predicted compression, an appropriate compression algorithm would need to be developed. But this can act as a guide for how well the compression could do. If all of the probabilities were known for the data, then entropy would give a lower bound on the amount of compression to be expected. As higher order probabilities are used, the predicted compression will become closer to the entropy bound.

The above ideas of data compression and entropy will now be applied to Telemetry data.

### **Test Data**

Thirteen actual telemetry data files were obtained from Vern Diekman at TYBRIN (1) through the Advanced Range Telemetry (ARTM) group. The data were then analyzed to find the 4 bit, 8 bit, and 12 bit entropies. The entropy for a set of data is given by:

$$H(S) = -\lim_{n \to \infty} \frac{1}{n} \sum_{i_1=1}^{m} \sum_{i_2=1}^{m} \dots \sum_{i_n=1}^{m} \{ P(X_1 = i_1, X_2 = i_2, \dots, X_n = i_n) \bullet \log P(X_1 = i_1, X_2 = i_2, \dots, X_n = i_n) \}$$
(1)

Where H(S) is the entropy of the source (the data)

 $X_i$  are the elements of all possible sequences of the data. The  $X_i$  can be bits, symbols, or words.

n =the length of the sequence

P is the probability

m = the size of the alphabet used for coding; for binary data, m=2, for words of 4 bits in length,

$$m=16$$
, etc.

To find the 4-bit entropy, all possible combinations of four elements from the binary alphabet were found. The frequency of occurrence of each of these 4 bit words was found. This frequency was used as an estimate of the probability of occurrence for each of these words. From these probabilities, the estimate for the 4 bit entropy was found using equation 1 where n=4 and m=2. For the 8-bit entropy, 256 different words are possible, and for the 12-bit entropy, 4096 words are possible. It can be seen that letting n approach infinity will quickly become impractical. The formats for each data set varied. Some of the data were coded into words of 10 bits, some 12 bits, etc. Plots and statistics for each of the data sets are in the appendix. A summary of the data statistics is given below:

	Data Set Entropies and Word Size						
Data Set	Data word size	4 bit	8 bit	12 bit	#bits/file		
	In bits	Entropy	Entropy	Entropy			
SDS001	12	3.9	7.5	10.3	139536000		
SDS002	12	3.3	6.0	7.5	94239360		
SDS003	12	3.8	7.0	9.0	157352160		
SDS004	10	3.4	5.9	7.3	496743000		
SDS005	10	3.6	6.6	8.6	1234710000		
SDS006	10	3.7	5.9	7.6	890556000		
SDS007	10	2.9	5.9	7.5	2347503000		
SDS008	12	2.6	4.2	4.7	1105437696		

Data Set Entropies and Word Size						
Data Set	Data word size	4 bit	8 bit	12 bit	#bits/file	
	In bits	Entropy	Entropy	Entropy		
SDS009	12	3.2	5.8	6.9	1102886400	
SDS010	12	2.7	4.3	4.8	1100703744	
SDS011	12	2.8	4.9	5.9	568813056	
SDS012	16	2.5	3.7	5.2	2193232356	
SDS013	24	2.8	3.7	4.6	3443281920	

To determine the amount of compression that should be possible, the entropy per number of bits must be used. Hence % compression for k bit entropies = (1-(k bit entropy))\*100. The amount of possible compression for each data set can then be found. If the k bit entropy is equal to the entropy, then the predicted compression will be a lower bound for all data compression techniques. A plot of the predicted compression from the calculated entropies is given in Figure 1. It can be seen that the compression increases as the number of bits per symbol is increased. This indicates that the entropies do not yet equal the entropy for the data sets. Consequently, compression techniques should be able to achieve values better than these predicted values.

The Huffman, an Adaptive Huffman, Arithmetic, and Lempel-Ziv compression algorithms were applied using programs from Mark Nelson's text [2]. The Huffman codes and Arithmetic codes use an 8-bit word length in the code. Two variations of the Lempel-Ziv algorithm were used. The LZSS uses a pair of values to indicate the location of the match and the length of the match in the dictionary. The LZW algorithm involves only sending one element instead of a pair of elements, and using a start up alphabet in the dictionary consisting of all the letters of the source alphabet. The percent compression for each technique along with the predicted compression is given in the following table.

	Data Compression Results							
Data	Huffman	Adapt.	LZSS	LZW	Arith-	% 4 bit	% 8 bit	% 12 bit
Set		Huffman			metic	Predicted	Predicted	predicted
						compress	compress	compress
SDS001	6.3	6.9	15.5	-9.9	6.6	2.5	6.3	14.2
SDS002	24.1	25.5	61.1	33.8	24.7	17.5	25.0	37.5
SDS003	11.5	15.5	39.7	-7.3	11.9	5.0	12.5	25.0
SDS004	25.1	27.7	50.2	11.5	25.5	15.0	26.3	39.2
SDS005	18.5	19.0	34.7	18.5	18.7	10.0	17.5	28.3
SDS006	25.1	25.9	40.2	32.5	25.4	7.5	26.3	36.7
SDS007	25.9	26.5	41.9	28.2	41.9	27.5	26.3	37.5
SDS008	46	48.3	71.0	53.9	46.7	35.0	47.5	60.8
SDS009	27.5	29.4	64.7	26.3	27.7	20.0	27.5	42.5
SDS010	45.2	47.5	68.9	52.7	45.9	32.5	46.3	60.0
SDS011	37.6	39.7	64.5	46.0	38.1	30.0	38.8	50.8
SDS012	51.9	51.9	65.9	63.7	51.9	37.5	53.8	56.7
SDS013	48.6	53.7	65.5	64.8	51.4	30.0	53.8	61.7

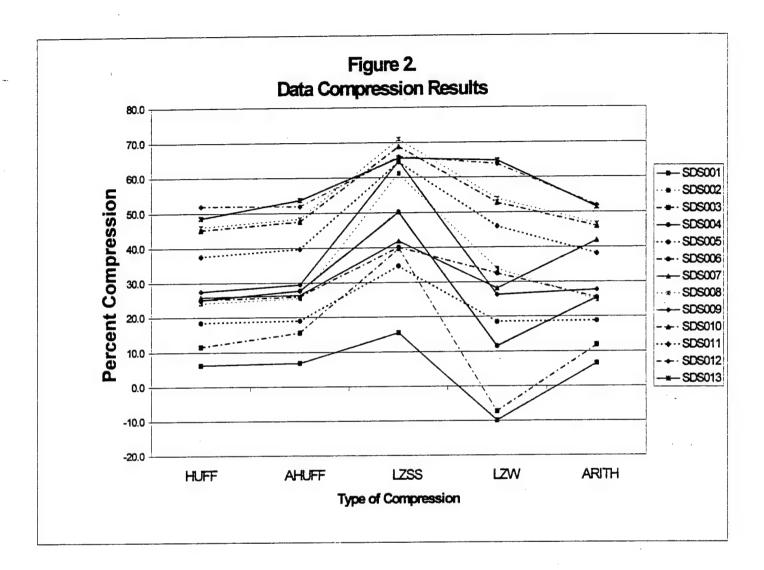

A negative with the compression value indicates that the file was expanded instead of compressed. It can be observed that each data file compressed differently. Figure 2 contains the plot of the results of the compression techniques. It can be seen from Figure 2 that certain files will compress very well. A 60% compression would mean that the file would take up less than half its original size. In all cases, there is at least one technique that provides compression of 10% or more. With the demands on spectra, even this little gain can be worth something. Since the Huffman and Arithmetic codes that were tried work with 8 bit word sizes, if the compression obtained by these techniques is compared with the 8-bit entropy, we see a very close match. All but 2 of the results are within 10% or less of the 8 bit entropy. Since the LZ algorithms achieve larger compression than this indicates, the 8-bit word size is not the best choice and that this 8-bit entropy is not the true entropy. Also, since the k bit entropies continue to increase with k, this also indicates that the actual entropy has yet to be found. Hence even larger compressions can be expected.

The Rice data compression algorithm was also tried. The results were discouraging. Instead of any compression, files were either expanded or were unable to decode to regain the original file. The main problem with the Rice algorithm is that is was designed specifically for images. The next thing tried was to modify the Rice code written by UNM to run with variable word length, and variable number of words per frame. This was found to be much more work because of the following problems:

- 1. The code is written and optimized to deal with image files, not telemetry data. This causes several "domino-effect" problems.
- 2. A "long" (32-bit variable) is used to keep track of the number of pixels (bits in our case) in a file. The largest value possible for a "long" is 2,147,483,647. So if a file size ever exceeds 2,147,483,647 bits (268,435,456 bytes = approx. 256 Megabytes), we would hit this limitation one telemetry file exceeds this limit.
- 3. ARTM telemetry is organized in frames with length of 200 words each. The UNM code (without modification) doesn't support this frame size or structure.
- 4. As said in a comment on line 3734 of rice.c (UNM code) the hardware (and thus the C code that simulates the chip) is limited to 64 blocks per scanline.
- 5. There also seems to be a magic number of 64 when it comes to the "pixels per block" command-line option of the compression program. When this option (-j <integer number here>) is set to 64 or less, there is no problem compressing or UNCOMPRESSING the file. When it is set to >64 there are no problems compressing the file, by when the file is UNCOMPRESSED, the uncompression part of the program gives an error message and halts. Also, the UNM code truncates the data frame if it is at the end of the file and its length is less than a complete scan line.

Noting these problems, the task of re-writing the code was undertaken, but time ran out before the task was completed. In an effort to decide whether this work would be worth the effort, other work was investigated.

In data compression classes at NMSU, students have applied various compression techniques to data. One student even added errors to see the effect errors would have on a compressed file. In an effort to see how well the compression could work, the results for an image is summarized below (3):

Compression	%	Channel Error	Errors	Comments
Algorithm	Compression	rate	made	
None	0%	1x10 <sup>-6</sup>	1	Can't notice error
None	0%	1x10 <sup>-1</sup>	58	Slight speckling
None	0%	1x10 <sup>-2</sup>	5022	Lots of speckles
Huffman	12%	1x10 <sup>-6</sup>	1	Shift in image
Huffman	12%	1x10 <sup>-4</sup>	42	Distorted, but
				recognizable
Huffman	12%	1x10 <sup>-2</sup>	4562	Decoder failed
Ziv-Lempel	3%	1x10 <sup>-6</sup>	1	Can't notice error
Ziv-Lempel	3%	1x10 <sup>-4</sup>	58	Highly distorted
Ziv-Lempel	3%	1x10 <sup>-2</sup>	4981	Decoder failed
Arithmetic	13%	1x10 <sup>-6</sup>	1	Decoder failed
Arithmetic	13%	1x10 <sup>-4</sup>	58	Decoder failed
Arithmetic	13%	1x10 <sup>-2</sup>	4505	Decoder failed
Rice	22%	1x10 <sup>-6</sup>	1	Decoder failed
Rice	22%	1x10 <sup>-4</sup>	5	Decoder failed
Rice	22%	1x10 <sup>-2</sup>	32	Decoder failed

From this table, it is obvious that single errors with compressed data can be disastrous. It can also be seen that when the Rice algorithm is used for images (for which it was designed), the compression is almost doubled. If the Rice algorithm can be adapted to handle 10, 12, 16 and 24 bits per word, and handle variable word sizes per frame (40, 128, 160, 200, 256, 300 etc) then the correlations of the data could be used to help reduce the file size. Since the data from one frame to another would be similar, taking advantage of these similarities should aid in the compression of the data. One way the Rice algorithm uses to reduce data correlation is to subtract the following symbol from the previous one. This works well for images, but not telemetry. In telemetry an entire frame would need to be subtracted from the following frames to reduce the correlation. The Rice algorithm is not currently set up to handle the variable frame sizes needed.

### Channel Error Simulations

### Error Sample File Description

Error files were obtained from Bert Carner at Synthesys Research (4) through ARTM for channel error simulations.

#### **General Conditions:**

Frequency: L band

Purpose of test: A/B comparison of FM and FQPSK-B @ 1 Mb/s

TX power: nine Watts, each transmitter

TX antenna pattern: well behaved omni patterns on belly of aircraft, single antenna

RX antenna: 8-foot dish, bldg 5790

Receivers: Microdyne model 700, narrowband, IF BW 1 MHz, single channel, i.e., NO

COMBINING.

### Sample point conditions:

Straight and level flight, Black Mountain corridor, 5k foot pressure altitude, approximately 2500 foot AGL, 200 Kt indicated airspeed

The two points represent classic multipath events. In this case there are at least three rays. There is a strong short delay ray (10-20 nsec range) and a weak long delay influence (in the range of 2-5 usec)

The main event in each file lasts about 1.5-2 seconds and the null depth is deep, at least 30 dB. The slant range is only about 40 miles, very strong signal conditions (Eb/No greater than 20 dB).

Two representative files were used to demonstrate the effect of the errors on the compressed files. For the data files SDS008, and SDS007 we have the following results:

### **BERA Simulation Results**

File name	Compressed?	Num Errors	Num Bits	BER
Sds008.dat	No	3	1105437696	2.713857e-009
Sds008.dat	Yes	2212390	8650752	0.2557
Sds007.dat	No	10	2.3475e+009	4.2599e-009
Sds007.dat	Yes	218	2.3475e+009	9.2865e-008

The compression algorithm used for compression on the above was the Ziv-Lempel algorithm (since it tends to give the best compression results). Here, the errors can cause major problems. Why does it create so many more errors in the compressed case? That is based on how the individual methods of compression work. With Ziv-Lempel (a dictionary based scheme), an error in the data, means the error will appear in the dictionary and so affect other code words. So, in the case of SDS008, the original three errors could expand to 2212390 errors as the errors go through the dictionary formed by the compression algorithm. However, if channel coding is used, these problems can be avoided. Other ways to prevent the propagation of errors is to reset the code after so many bits and restart the code.

### **Channel Coding**

Looking at the SDS008 case where 3 errors occur in the original file, channel coding would be able to eliminate any errors. A BCH code (1023, 973) can correct 5 errors (5). The 973 is the number of incoming bits to be channel coded and the 1023 is the number of bits sent. For each 973 bits input into the coder, the coder will add 50 bits so that it can find up to and including 5 errors per 1023 bits received. For this file, 8891 blocks

will need to be channel coded, giving a total of 9,095,302 bits to be added back into the file to eliminate the errors caused by the channel. Still at this rate, the amount of compression would be:

Compression ratio =  $\{1-(8,650,752+9,095,302)/(1,105,437,696)\}$  x100 = 98%

This still gives a sizeable amount of compression, and ensures protection from the channel. There are many different types of channel noise and each can treated using different techniques. BYU is currently working of ways of handling the channel effects that are pertinent to the problems encountered by the military.

### **Conclusions**

Data compression is a viable option to aid in reducing or maintaining bandwidth. Even with channel errors figured in, the compression achieved is worth the effort involved. Significant compression can be achieved through off the shelf technology. Even more compression should be obtainable with modifications of the Rice algorithm.

### **Acknowledgements:**

The author greatly appreciates the help received from the students who participated in this project and the people at ARTM (Chuck Irving and Vincent Schiappi) for their help and encouragement, Warner Miller at NASA for his help in obtaining the Rice coding, Gary Maki (University of New Mexico) for helping with the Rice coding, AFOSR for their support of this project, and especially Vern Diekman at TYBRIN for his help with the data sets.

### Computer Programs Appendix

James Woods wrote a lot of C code to examine the statistics of the data files and lay the preliminary work for the compression algorithms. The data and the initial data reading programs were obtained from Vernon Diekmann, at TYBRIN a subcontractor to Edward's Air Force Base. Some of the programs written by Vern Diekmann were modified slightly and are included in the list of programs below. The compression algorithms used were from Mark Nelson's book, except for the Rice algorithm, which was obtained through NASA and the University of New Mexico. A listing of the programs written by James Woods and a brief description of what they do is given below:

<u>COMPRICE</u>=> This program allows you to compare a file that has been run through rice to another file.

COMP2, COMP6 => This program just compares two files on your hard drive.

<u>COMP3CD</u> => Takes a file from the CD and compares it to one from the hard drive.

<u>COUNT12</u> => Counts 12 words configurations from the hard drive.

<u>FRAMAV</u> => Finds the average frame, the most popular frame.

FRAMINU1=> Takes the first frame and minuses it from the other frames.

FRAMMINU=>Takes a frame that was saved in another file and minuses it from the data file.

<u>IMPROVE</u>=>Same thing as display but from the hard drive.

NEGATIVE=>Minuses the frames without negatives.

NEW TWO=>Counts the different configurations of 4 and 8 bits from the hard drive.

READ1=>Will let you read any data file you want to put in.

TEN\_GREA => Counts the different configuration of 10 bits from the CD.

TWOONE=>Counts the different configurations of 4 and 8 bit from the hard drive.

TWOONECD=>Counts the different configurations of 4 and 8 from the CD.

WORD=>Counts the different configurations of 12 bits from the hard drive.

<u>WORDCD</u>=>Counts the different configurations of 12 bits from the CD.

The FRAM files were to see if using the Rice algorithm where the frames are subtracted would be viable. We ran into some limits of the students' programming abilities at this point and didn't successfully recreate the files we were working with – this was due to mapping the negative data values into the positive values. These programs should not be run without fixing the mapping problem.

The Two and Word programs were used to obtain the probability densities and then the entropies of the individual files.

The program files are on the following pages.

} /* End Main */
```

Shakti Davis wrote code to implement the channel simulations using the error files supplied by TYBRIN. The compression algorithm (lzss is from the Mark Nelson data compression book). These computer programs and instructions are listed below:

## Documentation for BERA Simulations:

To run a BERA simulation, open MATLAB and type "bera\_sim" at the command prompt. This should bring up a dialog box in which you can specify the transmit data file, the receive data file and whether you want the data to be compressed (with lzss) before the errors are injected. The last parameter, channel coding isn't implemented yet. To get the simulation started, you can either hit OK to accept the default parameters, or you can change any of the first three parameters. For the filenames, I would recommend giving the full path name (e.g. g:\sdsdata\sds008c.dat instead of just sds008c.dat) to insure that the simulation uses the correct file. Notice that the files can be read from the CD ROM drive, so you won't have to copy the files to the harddrive. Please be patient with the simulation because it may take several minutes to complete. If, however, the simulation is running and no harddrive activity occurs for several minutes, then the program may have frozen. In this case, I would suggest hitting CTRL-ALT-DEL and ending the MATLAB session.

The simulation is composed of several files acting on the data files. First, the "BERA\_sim.m" MATLAB file collects the simulation parameters from the user and determines whether the data file should be compressed. If the user indicated "yes" for compression, then the C-file lzss.c is used to compress the file. This is possible by compiling the C file as a MEX function. To compile the lzss.c file as a MEX file, do the following:

- 1. Open MATLAB
- 2. From the prompt, change the working directory path to D:\stats\simulink simulation\lzss which is where the C compression code resides
  - >> cd 'D:\stats\simulink simulation\lzss'
- 3. Compile the compression routine as a MEX file:

>>mex -DMATLAB -output 'd:\stats\simulink simulation\lzss\_c' main-c.c lzss.c bitio.c errhand.c

this creates a file called lzss\_c.dll in the d:\stats\simulink simulation\ directory that can be called from MATLAB

4. Use this function in a MATLAB script as a normal function call >>lzss c('SDS001c.dat','SDS001c.cmp');

So the BERA\_sim file compiles the input data file using this lzss\_c MEX function and moves on to the next step which is to process the BERA file. The processing is also done in a C program that was compiled as a MEX function. The C program is called procBERA.c and is located at d:\stats\simulink simulation\. To compile this program as a MEX file, do the following:

- 1. Open MATLAB
- 2. From the prompt, change the working directory path to D:\stats\simulink simulation which is where the procBERA C source code resides
  - >> cd 'D:\stats\simulink simulation\lzss'
- 3. Compile the compression routine as a MEX file:

  >>mex -DMATLAB -output 'd:\stats\simulink simulation\procbera' procbera.c

this creates a file called procbera.dll in the d:\stats\simulink simulation\ directory that can be called from MATLAB

4. Use this function in a MATLAB script as a normal function call >>procBERA('d:\stats\flight2bera\F02f\_02\_M12\_O28.bin', 'd:\stats\SDS001c.dat', 'd:\stats\rcvddata.bin')

This procBERA.dll function is called whether the compression is done or not, so this MEX function must exist in order to run the BERA simulation. The procBERA C code takes as inputs the name of the BERA error file, the name of the data input file, and the name of the data output file. Each of these files is opened and a replica of the data input file is copied to the data output file (this is the easiest way since there are so few errors relative to the number of correct bits). So originally the input data is equal to the output data. Next, the error file is read one entry at a time, where each error entry consists of the following 6-byte structure:

XOR word : bits 47-32 Event Byte : bits 31-24 24 bit counter : bits 23-0

For each error, an absolute position of that error is specified by the 24-bit counter, so the program goes to that position in the output data file. The XOR word contains a 1 at each error location, so once the output data file is correctly positioned, its data at that position (2-bytes), can be read, XOR-ed with the XOR word of the error entry, and written back to the data output file. This process is repeated for each error event in the BERA error file, or until the end of the data file is reached. The BERA files cover such a long transmit signal that the input data file is usually the limiting factor (e.g. the position specified by the error events are larger than the last position in the input data file). The event byte of the error structure is not used. While the error file is being processed, statistics about the file are collected. The three statistics which are returned to the MATLAB program are the bit-error-rate, the number of bits in error, and the total number of bits processed. To access these return values from the MATLAB call, simply call procBERA as follows:

[BER, numErrs, numBits] = procBERA (BERAfile, infile, outfile); and the bit error rate will be returned in the BER variable, the number of bits in error will be returned in the numErrs variable, and the total number of bits processed will bw returned in the numBits variable. If the simulation was specified to use the compression, then the data file that is created by the procBERA function must be decompressed using the lzss\_e MEX function (compiled the same way as the lzss\_c MEX function but instead of main-c.c use main-e.c). After the file is decompressed, it can be compared with the original data file and the true bit-error rate can be determined.

## BERA simulation program:

```
&Simulation using BERA files
% prompt for data file names
Prompts = { 'Enter the BERA filename:',...

/\* The objective of this program is to show how a BitAlyzer 25 Error File could be read using a simple program written in C. To understand this program the user must be familiar with the BitAlyzer error file format.

This program reads an error file and computes the total number of errors and the total error free interval.

For further information on writing programs to access error file data or error file format specifications please contact: SyntheSys Research, Inc. at 650-364-1853

Modified 11/18/99 -- S.D.

Now this program locates the errors and actually XORs the error bits with the true data. The resulting file can then be compared to the original data file for error analysis.

Syntax: procBERA BERAfile binarydatafile outputfile

### Notes from BYU:

The BitAlyzer stores it's data in 6 byte chunks.

XOR word : bits 47-32 Event Byte : bits 31-24 24 bit counter : bits 23-0

Because the data was written by a PC, and we were doing our work on Unix boxes, we had a little-endian big-endian problem (i.e. the byte addressing in the file is opposite between the PC and Unix boxes.) To overcome this problem I just read each byte out individually, and processed them the way I wanted. I hope that the documentation in the code is clear. Another reason to open the data in Byte chucks is since the data is 6 Bytes long, my attempts to try and read a 6 Byte block were actually executed as a read of 6 Bytes, then skip to the next word, i.e. two bytes later. So I was losing data. I could tell I was having problems because I was comparing it to a known file.

24 bit POSITION (bit pos: 0..23)

These 24 bits hold a count (in 16 bit words) of user clocks. For example, an error in the 100th serial bit of a serial stream would have POSITION count of 6 indicating an error presence in the 7th 16 bit word. To find which exact bit of the word was in error, one would look at which bit in the XOR word was a logical "1" (mismatch). In this example, it would be the 4th bit. It is guaranteed that at least one event will occur per the 16,777,218 counts of the 24 bit counter to allow a software implementation of a larger counter.

( The guaranteed event promised to detect the clock rollover is that the 24 bit counter reads 2, and the XOR word is all zeros. So all I did to detect clock roll over was to see if one the current clock value was less than the previous.)

bits EVENT (bit pos: 24..31)

Four of the eight bits in this byte are modifiers to the event type. These modifiers are orthogonal in that one event could have several modifiers. For example, an event could have errors AND be a used as a marker AND be a RESYNC location. The other four bits in the event byte are used to indicate the exact bit position in which the marker event occurred. The marker position bits are only valid when the Marker event bit is set to 1. The modifiers are defined as follows:

b0 (bit pos: 24)
b1 (bit pos: 25)
b2 (bit pos: 26)
b3 (bit pos: 27)
b4-b7 (bit pos: 28-31)
BM-Marker (Rear Panel)
P-Pattern Cycle Marker (Internal)
R-Start Resynchronization Event
S-Begin Error Squelch Event
Bit position of the Marker within this event
word.

Marker: This is an internal pole once every second (for Edward's Air Force base). We didn't worry about this event.

Pattern: The BitAlyzer has acquired the pattern, and is now synched up. NOTE: The PATTERN event might only happen once in a file, Usually at the beginning of a file.

Resync: The BitAlyzer25 has reached a threshold of errors where it no longer is able to hold pattern, and now is in the process of trying to acquire pattern.

Squelch: To many errors have occurred and have filled the BitAlyzer internal buffer. The BitAlyzer empties the buffer, and then resumes detecting and writing errors to the file. During the squelch, errors are NOT recorded. The buffer is 2 k words, and is controlled by software.

Okay, now here comes some iffy stuff. When I asked them how to detect when the events were over, they told be the following. They said that for the Resync or Squelch to end, the ZERO event had to occur. The zero event was defined to be that the XOR word was all zeros, and that the EVENT Byte had to be all zeros. I used this in my code, but when I would compare it to known data I could never match up the results. So I used the fact that they said that no errors were recorded during a Squelch event, and some trial and error to decide for myself that the way to detect that the events are over if bits 24-27 are all zero, i.e. the marker events are zero. I did this and presto, my data matched the output their expensive code said that it should. I still have a small discrepancy on the number of bits lost in a squelch event, but the correct number of squelch events is calculated. I'm not sure if the discrepancy comes from the fact that I window the data or not. It's been 6 months since I've worked on the problem, and my memory is rusty on the details. The real trick to figuring out the event structure was to compare it to a known file.

The man to contact at Synthesis Research is a guy called Bert Carner (650) 364-1853, Bert\_Carner@synthesysresearch.com. Tell him that you're working with Edward's Air Force Base, and he'll probably be helpful.

ActualErrs, int* ActualBits)
* Purpose/Descr.
* Count the total number of bits processed and the total number of
* errors recorded. Also xor the errors with the original data file
* to produce a new file with errors in the positions described by the
* error file.
* Input:
* FILE * fin - pointer to the error event file to be processed
* FILE * fdata -- pointer to the original error-free data file
* FILE * fout -- pointer to a replica of the data file. This file will
                                      be modified with the bit errors
                       -- double pointer to variable that will receive the actual Bit Error Rate
 * double * BER
       int * ActualErrs -- int pointer to the variable that will receive the actual number of errors
       int * ActualBits -- int pointer to the variable that will receive the actual number of bits
processed
 * Output: void
 * Return Codes: None
